Abstract

Voice Activity Detection (VAD) is considered as an important pre-processing step in speech processing systems such as speech enhancement, speech recognition, gender and age identification. VAD helps in reducing the time required to process speech data and to improve final system accuracy by focusing the work on the voiced part of the speech. An automatic technique for VAD using Fuzzy-Neuro technique (FN-AVAD) is presented in this paper. The aim of this work is to alleviate the problem of choosing the best threshold value in traditional VAD methods and achieves automaticity by combining fuzzy clustering and machine learning techniques. Four features are extracted from each speech segment, which are short term energy, zero-crossing rate, autocorrelation, and log energy. A modified version of fuzzy C-Means is then used to cluster speech segments into three clusters; two clusters for voice and one for unvoiced. After that, three feed forward neural networks are trained to adjust their weights, in which each network represents one cluster. To make the final decision regarding the class type of a given speech segment, the membership degrees of this segment in all clusters along with neural networks' decisions are given to a defuzzification step which finally gives the class type of that segment. The proposed FN-AVAD is tested on the public multimodal emotion database, Surrey Audio-Visual Expressed Emotion (SAVEE), and the error rate was 2.08%. The achieved results are comparable to the results achieved by the current published works in the literature.

Keywords: Defuzzification, Fuzzy clustering, Neural network, Speech signal, Voice activity detection.
1. Introduction

Speech signal is one of the most important signals that contain information. It includes words, emotions, intention, accent, dialect, age, speaker identity, gender, health status of the speaker, etc. [1, 2]. However, building applications to extract information conveyed within the speech signal need efficient feature extraction techniques. These features need to be extracted from the voiced part as it contains the important speech or speaker specific attributes [3]. Distinguishing of voiced speech from silence and background noise is called Voice Activity Detection (VAD). VAD is mainly used to reduce the amount of time required to process the data by removing undesired parts like silence, pause and any non-speech activity from speech signal. It is also useful for improving system computation capabilities by reducing the dimensionality of the extracted features [4, 5].

Statistical and pattern recognition approaches have been applied for deciding the class of the given segment of a speech signal [6]. Most of these methods are based on extracting a feature from speech segments to make the decision by comparing the value of that feature with a pre-defined threshold. This feature can be Mel-Frequency Cepstral Coefficient (MFCC), Zero Crossing Rate (ZCR), Cepstral domain peak, Short Term Energy (STE), or harmonic to noise ratio, etc. [7]. However, these features have their own disadvantages regarding determining the threshold in an ad hoc basis. For example, STE uses the fact that energy in a voiced segment is greater in silence/unvoiced segment. But it is not known in advance, what is the optimal threshold value that should be for precise classification, because it varies from case to case [6].

In addition, each feature has its own limitations thus, the methods proposed in the literature attempted to use a combination of features for voiced/unvoiced decision. Radmard et al. [7] have presented an approach for VAD based on the analysis of zero crossing rate, Cepstral peak, and Auto Correlation Function (ACF) peak of the speech signal segments by clustering the extracted features using K-Means algorithm with K=3 (one cluster for unvoiced and two clusters for voiced). 821 frames of speech taken from Texas Instruments/Massachusetts Institute of Technology (TIMIT) were used for testing purpose. The total error rate for voiced segments was 4.8% while the error rate for unvoiced segments was 1.1% [7].

Algabri et al. [8] used STE and ZCR with fuzzy logic to control voiced/unvoiced classification of speech segments. An error ratio equal to 2.5 % was achieved using the Arabic digits of the KSU database [8]. Roy et al. [9] decomposed the speech signal into low-frequency and high-frequency components using wavelet transform and then compute the entropy-based thresholds for these components. Two types of thresholds have been used: low-frequency thresholds (for voiced speech segments) and the high-frequency thresholds (for the unvoiced speech segments). The Ryerson Audio-Visual Database of Emotional Speech and Song (RAVDESS) database was used for testing purpose and the overall accuracy was 99.3% for start-frame detection and 97.5% for end-frame detection [9]. Although the effort to find a solution for VAD problem started a long time ago and different methods have been proposed, the search continues because the accurate solution is still not found.

An automatic voiced activity detection using Fuzzy-Neuro technique (FN-AVAD) is presented in this paper. A combination of features is used to decide whether the given speech segment is voiced or unvoiced in an automatic fashion. Since the extracted features' values are not precise; it will be helpful to use Fuzzy-
Neuro technique by combining fuzzy C-Means clustering and neural network to more accurate results. Fuzzy concept allows feature approximation while neural network permits learning and behaviour reservation. The remainder of this paper is categorized as follows: In the next section, theoretical background for some of the methods used is presented. The proposed methodology is described in detail in Section 3. Section 4 illustrates the achieved results when applying the proposed method on the test database. Finally, conclusions and recommendations for future works are discussed in Section 5.

2. Theoretical Background

This section demonstrates the underlying theoretical concepts used by the proposed FN-AVAD method.

2.1. Speech framing and windowing

Generally, the sound production system of human speech needs about 12-30 milliseconds gap between two words when producing speech sound because the system needs that time to prepare itself to produce the next sound. So, it is required to break the signal into smaller short-time segments (frames). The size should be chosen within that range. In order to keep the continuity of frames, it’s necessary to retain some overlaps between the continue frames. This process is called framing process. The lengths of the frame, as well as the overlap ratio between successive signal frames are related to the problem at hand. After framing the speech signal, windowing process must be performed. Windowing is the process of multiplying a waveform of speech signal segment by a time window of a given shape, to stress pre-defined characteristics of the signal and smooth the discontinuities at the beginning and end of the sampled signal. Some of the windowing functions used in speech analysis are rectangular window, Hanning window, Bartlett window, Blackman window, Kaiser window, Hamming window, etc. [10].

2.2. Speech characteristics

To separate voiced from unvoiced speech, discriminative features must be extracted from each speech frame, and these features must obey with the following speech characteristics [11, 12]:

- Lowest energy presents in the unvoiced speech waveform when compared to voiced speech.
- Less number of zero crossings associated with the voiced waveform when compared to unvoiced speech.
- No correlation among successive samples in the speech waveform for unvoiced speech.
- The absence of any signal characteristics in unvoiced speech.

2.3. Speech normalization

Data normalization is mainly used to allow the comparison of corresponding data values for different datasets in a way that eliminates the side effects of certain gross-influences [13]. Speech attribute normalization is required due to the following reasons:

(i) Different persons may speak with different loudness levels.
(ii) The speech may be recorded with different distances from the microphone which in effect reduces the level of the recorded sound.

(iii) The extracted features may have different scales that will affect the learning process of the classifier.

2.4. Fuzzy C-Means clustering algorithm

Fuzzy clustering, which is frequently used in pattern recognition, uses the concepts of the field of fuzzy logic and fuzzy set theory. Fuzzy set theory allows an element to belong to a set with a degree of membership between 0 and 1. Fuzzy clustering consists of a collection of C clusters, \( C_1, C_2, \ldots, C_C \), and a membership matrix \( \mu = \mu_{ij} \in [0,1] \), for \( i = 1 \ldots K \) and \( j = 1 \ldots C \), where each element \( \mu_{ij} \) represents the degree of membership of object \( i \) in cluster \( C_j \). It is based on minimization of the following objective function [14]:

\[
J_m = \sum_{i=1}^{K} \sum_{j=1}^{C} \mu_{ij}^m \|X_i - C_j\|^2 , 1 \leq m \leq \infty
\]  

(1)

where \( K \) is number of data elements, \( C \) is number of clusters, \( m \) is any real number greater than 1 which represents the intensity of fuzzification, \( X_i \) is the \( i \)-th of \( d \)-dimensional measured data item, \( C_j \) is the \( d \)-dimension centre of the cluster, \( \mu_{ij} \) is the degree of membership of \( X_i \) in the cluster \( j \), and \( \| \| \) is any similarity measure between data item and cluster centre. Fuzzy partitioning is carried out through an iterative process. In each iteration, the membership \( \mu_{ij} \) and the cluster centres \( C_j \) are updated as follows [14]:

\[
\mu_{ij} = \frac{1}{\sum_{z=1}^{C} \left( \frac{\|X_i - C_j\|^2}{\|X_i - C_z\|^2} \right)^{\frac{m-2}{m-1}}} 
\]

(2)

\[
C_j = \frac{\sum_{i=1}^{K} \mu_{ij}^m x_i}{\sum_{i=1}^{K} \mu_{ij}^m} 
\]

(3)

2.5. Feed forward neural networks

Machine learning algorithms perform specific tasks by generalization from a set of data samples. An example of machine learning algorithms is Artificial Neural Network (ANN). ANN is interconnection of neurons in which each neuron can be defined as follows [15]:

\[
O(X) = g(\sum_{i=0}^{K} W_i X_i) + b
\]

(4)

where, \( X \) is a neuron with \( K \) input \((X_0, \ldots, X_K)\), \( O(X) \) is the output of \( X \), and \( W_i \) are weights that are given for each data input \((W_0, \ldots, W_K)\). \( g \) is an activation function that indicates how powerful the output should be from the neuron, based on the sum of the input, and \( b \) is a bias [16]. In feed forward neural network, the input is fed forward through the network to update the weights between network neurons. The training phase in this network topology is called “back propagation”, where the error is backward propagated to adjust the weights [17].

3. The Proposed FN-AVAD Method

The proposed FN-AVAD method consists of two important stages: training stage and testing stage. In training stage, the ANNs are trained with the extracted features...
for the three clusters that are resulted from fuzzy clustering. Training stage involves five steps: (1) framing and windowing, (2) feature extraction, (3) feature normalization, (4) fuzzy clustering and (5) ANNs training. The purpose of testing stage is to classify the short time segments of the speech into either voiced or unvoiced classes using the pre-trained networks. Testing stage consists of six steps: (1) framing and windowing, (2) feature extraction, (3) feature normalization, (4) fuzzy clustering, (5) ANNs testing, and (6) defuzzification. Figure 1 demonstrates the general view of the proposed FN-AVAD method.

Fig. 1. General view of the proposed FN-AVAD method.

3.1. Training stage

3.1.1. Framing and windowing step

Hamming window is used for windowing process because it is simple and the frequency ripples at the ends of the window can be avoided. The mathematical representation of hamming window can be defined as in Eq. (5) [1].

\[
w[n] = \begin{cases} 
0.54 - 0.46 \cos \left( \frac{2\pi n}{L} \right) & 0 \leq n \leq L \\ 
0 & \text{otherwise}
\end{cases}
\] (5)

where \(L\) is the number of samples in each frame, \(n\) is the number of the frame under processing and \(w[n]\) is the result of applying windowing process. Window length used in this work is 12 milliseconds with 50% overlapping ratio because these values gave the best framing results by trial and error.

3.1.2. Feature extraction step

In feature extraction step, the discriminated features are extracted from each speech frame. To avoid the problems of using a single feature, four features have been used in this work which is STE, ZCR, ACF and Log Energy (LE). These features are extracted because they obey speech characteristics mentioned in Section 2.2.
(a) **Short Term Energy (STE)**

Short-term energy represents the amount of energy in the speech signal at a specific instance of time. The STE of a voiced signal is always much greater than that of unvoiced signal. STE can be defined as in Eq. (6) [11].

\[ \text{STE}(n) = \frac{1}{L} \sum_{i=0}^{L-1} X_i^2 \]  

(6)

where, \( n \) is the number of the frame under processing, \( L \) is the length of speech frame and \( X_i \) is the \( i^{th} \) sample in frame \( (n) \).

(b) **Zero Crossing Rate (ZCR)**

Zero-crossing rate is a measure of the number of times amplitude of a speech signal crosses through a value of zero within a given interval of time. In case of unvoiced speech, the signal crosses zero more number of times than voiced speech. For silent regions, ZCR is near zero. ZCR can be defined as in Eq. (7) [4].

\[ \text{ZCR}(n) = \frac{1}{2(L-1)} \sum_{i=0}^{L-1} \text{sgn} (X_{i+1}) - \text{sgn} (X_i) \]  

(7)

and, \( \text{sgn}(X_i) = \begin{cases} 1, & \text{if } X_i \geq 0 \\ 0, & \text{otherwise} \end{cases} \)  

(8)

where, \( n \) is the number of the frame under processing, \( L \) is the length of speech frame and \( X_i \) is the \( i^{th} \) sample in frame \( (n) \).

(c) **Auto Correlation Function (ACF)**

The autocorrelation coefficient gives the correlation between the adjacent samples of the signal which usually varies between -1 and +1. The value of ACF for voiced signal is close to unity (1 or -1) because of the frequency concentration in the low frequencies while it is close to zero for unvoiced signal. ACF is defined as shown in Eq. (9) [6].

\[ \text{ACF}(n) = \frac{\sum_{i=1}^{L} X_i X_{i+1}}{(\sum_{i=0}^{L-1} X_i^2)(\sum_{i=0}^{L-1} X_i^2)} \]  

(9)

where, \( n \) is the number of the frame under processing, \( L \) is the length of speech frame and \( X_i \) is the \( i^{th} \) sample in frame \( (n) \).

(d) **Log Energy (LE)**

Log energy (the decibel dB) is a measure of speech loudness with respect to humans' ears. Log-energy of frame \( (n) \) can be defined as in Eq. (10) [18].

\[ \text{LE}(n) = 10 \times \text{Log}_{10}(\epsilon + \frac{1}{L} \sum_{i=0}^{L-1} X_i^2) \]  

(10)

where, \( n \) is the number of the frame under processing, \( L \) is the length of speech frame, \( X_i \) is the \( i^{th} \) sample in frame \( (n) \) and \( \epsilon \) is any small number usually \( 10^{-6} \).

3.1.3. **Feature normalization step**

Feature normalization step is required to compensate the differences among various speech cases. Features are normalized to the range of [0-1] using Eq. (11) [13].
\[ V'_i = \left( \frac{V_i - \text{Mino}}{\text{Maxo} - \text{Mino}} \right) \ast (\text{Maxn} - \text{Minn}) + \text{Minn} \]  

(11)

where \( V_i \) and \( V'_i \) are the old and new data values, respectively, \( \text{Mino} \) and \( \text{Maxo} \) are the old range confines and \( \text{Minn} \) and \( \text{Maxn} \) are the new range confines.

### 3.1.4. Modified fuzzy C-Means

A modified version of Fuzzy C-Means is proposed in this work. The objective of the modifications is increasing the coherence of the resulted clusters through intensify the effect of very similar objects and reduce the effect of very far objects. These modifications can be outlined with the following points:

- Since the behaviors of the extracted features are known in advance, the initial value of clusters’ centers can be guessed. Clusters’ centers are set to a given range through searching the feature space for a sample that holds feature with value in that range. This will lead to a guided fuzzy C-Means.

- The number of used clusters is three. One cluster for unvoiced speech with the initial center within the range \([0.1-0.3]\). Two clusters for voiced speech with the initial centers equal to \([0.5-0.7]\) and \([0.8-1]\), respectively. STE feature is used for finding the best frame sample to be set as an initial center for each cluster.

- To ensure the coherent of the resulted clusters, the membership function of fuzzy C-Means is changed. The distance of the object \( (X_i) \) from the cluster center \( (C_j) \) is computed and compared with two values \((a_1 \) and \( a_2 \)). The proposed membership function can be defined as in Eq. (12):

\[
\mu_{ij} = \begin{cases} 
1 & \text{if } \left( |X_i - C_j| \right) \leq a_1 \\
0 & \text{if } \left( |X_i - C_j| \right) \geq a_2 \\
\frac{1}{\sum_{k=1}^{C} \left( \frac{|X_i - C_k|}{|X_i - C_j|} \right)^{m-1}} & \text{otherwise} 
\end{cases}
\]  

where: \( a_1 = \text{Min}_{1\text{sick}}\left\{ |X_i - C_j| \right\} + V_1 \), \( a_2 = \text{Max}_{1\text{sick}}\left\{ |X_i - C_j| \right\} \ast V_2 \) and \( V_1, V_2 \in [0-1] \).

In other words, if the object is very close to the cluster center (its’ distance less than or equal to \( a_1 \)) then its membership degree will be set to 1, to emphasis its contribution in cluster center calculation. Otherwise, if the object is so far from the cluster (its distance greater than or equal to \( a_2 \)) then it will be thrown out the cluster by setting its membership degree to be 0, to ensure it will not contribute in cluster center computation. Figure 2 demonstrates the idea of modified membership function proposed in this paper.

The output of fuzzy C-Means may contain samples with a very small membership degree for some clusters. If we considered each sample showed a membership degree greater than zero as a member of the cluster (even it has a very small membership degree), we will face a problem when training ANNs because the ANNs will show similar behavior and this will lead to incorrect classification of the given speech frame. To solve this problem, a parameter called “Fuzzification Ratio” with value ranged from 0 to 1 is added. The membership degree of each frame within each cluster is compared with this parameter. If the membership
degree of the given frame is greater than *Fuzzification Ratio* value, then it will be member of that cluster otherwise it will be discarded.

![Original function and modified function](image)

**Fig. 2.** Fuzzy C-Means membership function.

### 3.1.5. ANNs training

Since the extracted features are imprecise to make voiced/unvoiced decision, it will be helpful to use fuzzy and machine learning concepts to solve VAD problem as shown in Fig. 3.

![Fuzzy-neuro technique diagram](image)

**Fig. 3.** Fuzzy-neuro technique used for VAD problem solution.

Training step focuses on analyzing and interpreting the patterns and structures of each cluster to enable learning and decision making. Three feed forward neural networks with the following configuration are used (as shown in Fig. 4):

- **Number of nodes in input layer** = number of features = 4
- **Number of nodes in output layer** = 2 (for the binary representation of {1, 2, 3})
- **Number of nodes in hidden layer** = 2

Each network is trained with the frame samples of its' corresponding cluster. The training process aims at remembering the behavior of cluster members by
adjusting network weights’ values. The resulted weights of each network are then saved to a separate file, so it can be used in the testing stage.

![Fig. 4. ANN structure used in training step.](image)

### 3.2. Testing stage

In testing stage, the short time segments of a given speech signal is classified to either voiced or unvoiced speech. This can be done in six steps as shown in Fig. 1. Framing and windowing, feature extraction, feature normalization and fuzzy clustering steps are similar to their partners’ steps in the training stage. In the 5th step (ANNs testing step), each network is tested with the features extracted from the frame to be classified. The network returns either 0 (in case of the frame is not similar to the cluster member) or returns the cluster number (in case of similarity between the checked frame and its member). Finally, in defuzzification step, the membership degree of the given frame is compared with Fuzzification Ratio, if the former is greater than the latter then the corresponding ANN is tested to check whether the frame is similar to these clusters’ members. ANN’s decisions along with the frame membership degrees are inputted to center of gravity defuzzification method. The output for frame \( X \) can be computed as in Eq. (13):

\[
y = \frac{\sum_{i=1}^{3} \mu_{C_i}(X) \cdot ANN_i(X)}{\sum_{i=1}^{3} \frac{ANN_i(X)}{\mu_{C_i}(X)}}
\]

(13)

where \( \mu_{C_i}(X) \) is the membership degree of \( X \) to class \( C_i \), and \( ANN_i(X) \) is the output of neural network ANN, for input \( X \). The summation in Eq. (13) will repeat for three times because the proposed method consists of three clusters and three ANNs.

### 4. Experimental Results and Discussions

The proposed Fuzzy-Neuro VAD methodology is trained and tested on Surrey Audio-Visual Expressed Emotion (SAVEE) database. SAVEE includes recordings of seven different emotions for four male actors, a totally of 480 samples. The sentences are in British English utterances that chosen from the standard corpus of TIMIT. The data were recorded in a visual media lab with high quality audio-visual equipment. To
check the quality of the recorded videos, they were evaluated by ten subjects under audio, visual and audio-visual conditions [19].

Figure 5 shows the results of feature extraction and normalization steps for the four different features using an example speech signal from the SAVEE database.

Fig. 5. Feature extraction and normalization results.

Different experiments are conducted to find the best values for m, number of iterations, V1, V2 and Fuzzification parameters. The parameters settings that gave the best results were: $m=1.5$, number of iterations = 100, $V_1=0.06$, $V_2=0.9$, Fuzzification Ratio=0.5. Table 1 shows the memberships’ degrees of frames numbered from 80 to
100 for an example speech signal that achieved after clustering the signal using traditional fuzzy C-Means and modified fuzzy C-Means algorithm, respectively. As shown in the table, the membership degrees are set to 1 for the frames which are very close to the cluster center, while the membership degrees are set to 0 for the frames which are very far from the cluster.

Table 1. Traditional and modified fuzzy C-Means membership degree for the frames numbered from 80 to 100 for an example speech signal.

Emphasizing the effect of very close frames and reducing the effect of very far frames lead to more fine-tuned clusters' centers. Figure 6 demonstrates frames distribution of a sample speech signal using traditional and modified Fuzzy C-Means, for the four extracted features. The left image in the figure represents the traditional fuzzy C-Means while the right image represents the modified fuzzy C-Means. The figure clearly showed that modified fuzzy C-Means can get rid of far frames and preserve the coherence of the resulted clusters especially for ACF and LE features.

Table 2 illustrates the results of testing 20 frames (from 139-158) for an example speech signal. The table also shows values of the extracted features, membership degrees, neural networks' results and the final decision taken by defuzzification step. These frames are selected because they involve numerous frame types (i.e., voiced and unvoiced).
Fig. 6. The distribution of frames’ samples in the resulted clusters.
Table 2. Results of 20 frames (from 139 to 158) chosen from a sample speech signal.

Figure 7 shows the results of the proposed methodology when tested on three different speech signals with different speech loudness. The first image (with blue drawing) represents the original speech signal while the second image (with red circles) represents the frames which are selected as voiced parts. The third image (with green drawing) shows the final voiced part of the speech in which the frames with voiced class are gathered together in a new signal. The figure clearly demonstrates the effectiveness of the proposed FN-AVAD method.

The proposed FN-AVAD method is further evaluated using error rate measure as defined in Eq. (14) [7].

Error Rate = $\frac{TH-TC}{TH} \times 100$ (14)

where $TH$ is the number of voiced frames detected by the human and $TC$ is the number of voiced frames detected using the proposed method. The final error rate achieved by the proposed VAD method was 2.08%. Table 3 shows a comparison made between the proposed method and the current research works on the VAD problem along with method used and the achieved results. The table demonstrates the effectiveness of the proposed VAD method.

5. Conclusions and Future Work

An automatic Fuzzy-Neuro VAD (FN-AVAD) methodology has been presented in this paper to omit the need for proper threshold selection. A modified version of fuzzy C-Means helps in achieving features’ approximation by clustering speech frames into three clusters with membership degrees. On the other hand, neural networks work as a memory to remember the behaviour of each cluster by updating the network weights. The experimental results showed the effectiveness of the proposed FN-AVAD. As future work, features from spectral-domain can be extracted instead of time-domain features. In addition, to separate noise parts from silent parts, four clusters can be used with different initial ranges in which the noise has range laid between silent and voiced ranges. Recurrent deep learning techniques can also be utilized to take into account the time factor between successive frames.

Nomenclatures

- $ANN(X)$: Output of neural network $ANN$, for input $X$
- $b$: Neural network bias
- $C$: Number of clusters
- $C_j$: Centre of the cluster $j$
- $g$: Activation function
- $K$: Number of data elements
- $L$: Length of speech frame
- $m$: Intensity of fuzzification
- $Max_n$: Maximum value in new range confines
- $Max_o$: Maximum value in old range confines
- $Min_n$: Minimum value in new range confines
- $Min_o$: Minimum value in old range confines
- $n$: Number of the frame under processing
- $O(X)$: Neural network output for input $X$
- $TC$: Number of voiced frames detected using the proposed method
- $TH$: Number of voiced frames detected by the human

\[ \mu_{C_i}(X) \] Membership degree of \( X \) to class \( C_i \)

\[ \mu_{ij} \] Degree of membership of object \( i \) in cluster \( C_j \)

\( V_i \) Old data value

\( V_i' \) New data value

\( V_1 \) Maximum distance for emphasising the contribution of data element in cluster centre calculation

\( V_2 \) Minimum distance for outlier removal

\( W_i \) Weights that are given for each data input \( (W_0, \ldots, W_K) \)

\( X \) Data input with \( K \) elements \( (X_0, \ldots, X_K) \)

\( X_i \) Data element \( i \) in the input \( X \)

**Greek Symbols**

\( \varepsilon \) Any small number usually \( 10^{-6} \)

**Abbreviations**

- ACF: Auto Correlation Function
- ANN: Artificial Neural Network
- FN-AVAD: Automatic Voiced Activity Detection using Fuzzy-Neuro
- LE: Log Energy
- MFCC: Mel-Frequency Cepstral Coefficient
- RAVDESS: Ryerson Audio-Visual Database of Emotional Speech and Song
- SAVVEE: Surrey Audio-Visual Expressed Emotion
- STE: Short Term Energy
- TIMIT: Texas Instruments/Massachusetts Institute of Technology
- VAD: Voice Activity Detection
- ZCR: Zero Crossing Rate
